The young X-ray and gamma-ray-bright supernova remnant RXJ1713.7-3946 (SNR G347.3-0.5) is believed to be associated with molecular cores that lie within regions of the most intense TeV emission. Using the Mopra telescope, four of the densest cores were observed using high-critical density tracers such as CS($J=1-0, J=2-1$) and its isotopologue counterparts, NH₃(1,1) and (2,2) inversion transitions and N₂H+($J=1-0$) emission, confirming the presence of dense gas $>10^4 \text{cm}^{-3}$ in the region. The mass estimates for Core C range from $40M_{\odot}$ (from CS($J=1-0$)) to $80M_{\odot}$ (from NH₃ and N₂H+), an order of magnitude smaller than published mass estimates from CO($J=1-0$) observations. We also modelled the energy-dependent diffusion of cosmic-ray protons accelerated by RXJ1713.7-3946 into Core C, approximating the core with average density and magnetic field values. We find that for considerably suppressed diffusion coefficients (factors $\chi=10^{-3}$ down to 10^{-5} the galactic average), low energy cosmic-rays can be prevented from entering the inner core region. Such an effect could lead to characteristic spectral behaviour in the GeV to TeV gamma-ray and multi-keV X-ray fluxes across the core. These features may be measurable with future gamma-ray and multi-keV telescopes offering arcminute or better angular resolution, and can be a novel way to understand the level of cosmic-ray acceleration in RXJ1713.7-3946 and the transport properties of cosmic-rays in the dense molecular cores.

Comments: 17 pages, 13 figures and 5 tables. Accepted for publication in MNRAS 2012 February 17
