**ABSTRACT:** We used an array of ion-selective electrodes (oxygen [O<sub>2</sub>], hydrogen [H<sup>+</sup>], carbonate [CO<sub>3</sub><sup>2-</sup>], calcium [Ca<sup>2+</sup>], ammonium [NH<sub>4</sub><sup>+</sup>], and nitrate [NO<sub>3</sub><sup>-</sup>]) with a micromanipulator to study mineralization processes in the surface sediments in Lake Baikal. Concentration profiles at submillimeter resolution were measured in sediment cores from four depths (160-1,400 m) in the South Basin. Oxidation rates of organic carbon (C) estimated from O<sub>2</sub> and NO<sub>3</sub><sup>-</sup> profiles measured in March and July 2001 ranged between 2.2 and 4.9 mmol C m<sup>-2</sup> d<sup>-1</sup>. The characteristic shape of the O<sub>2</sub> profiles allowed separation of oxidation of organic carbon from reoxidation of reduced compounds at the oxic-anoxic boundary. Of the benthic carbon turnover, 60-75% was metabolized through oxic respiration and 11-28% through anoxic mineralization. The remainder (12-14%) was due to denitrification. Carbon dioxide (CO<sub>2</sub>) profiles calculated from O<sub>2</sub> agreed well with those from pH and CO<sub>3</sub><sup>2-</sup>, supporting the concept that oxic respiration was the prevailing mineralization pathway. Alkalinity balance calculated from flux rates of reduced compounds and bicarbonate (HCO<sub>3</sub><sup>-</sup>) calculated from pH and CO<sub>3</sub><sup>2-</sup> profiles showed that the sediment was a sink for alkalinity. The flux rates in the range of 0.13-1.0 mmol m<sup>-2</sup> d<sup>-1</sup> were caused by buffering the hydrogen ions (H<sup>+</sup>) generated from reoxidation processes of reduced compounds. Potential dark CO<sub>2</sub> assimilation by chemoautotrophic bacteria in the sediment was 0.03-0.1 mmol C m<sup>-2</sup> d<sup>-1</sup>. Because of the long O<sub>2</sub> exposure time of 25-2,500 yr, however, only 3-14% of the initially settled organic carbon was finally buried in the sediments, forming the paleolimnological record of Lake Baikal.
