摘要: 采用活性测试和氨气吸附、X射线衍射、X射线光电子能谱、紫外-可见漫反射吸收光谱、高倍透射电镜、原位漫反射傅里叶变换红外光谱和O₂脉冲吸附等研究了铈添加对Ag/Al₂O₃催化剂低温氨氧化性能的影响。结果表明, 适量铈的添加可以明显促进Ag/Al₂O₃催化剂的低温氨氧化活性, 且对催化剂的选择性影响不大。添加铈不仅可以促进Ag/Al₂O₃催化剂表面吸附和活化O₂的能力, 而且可促进催化剂表面对氨的解离吸附和活化。这是铈促进Ag/Al₂O₃催化剂低温氨氧化活性的主要原因。

Effects of Adding CeO₂ to Ag/Al₂O₃ Catalyst for Ammonia Oxidation at Low Temperatures

ZHANG Li, LIU Fudong^a, YU Yunbo, LIU Yongchun, ZHANG Changbin, HE Hong^b

State Key Laboratory of Environmental Chemistry and Ecotoxicology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100085, China

Abstract: The effects of adding CeO₂ to Ag/Al₂O₃ on the selective catalytic oxidation of ammonia to nitrogen were investigated by activity test and N₂ physisorption, X-ray diffraction, X-ray photoelectron spectroscopy, UV-Vis diffuse-reflectance spectroscopy, high resolution transmission electron microscopy, in situ diffuse reflectance infrared Fourier transform spectroscopy of NH₃ adsorption, and O₂-pulse adsorption. Adding a suitable amount of CeO₂ improved the catalytic activity of Ag/Al₂O₃ for NH₃ oxidation at temperatures below 160 °C, and slightly influenced N₂ selectivity by improving the catalyst's ability to adsorb and activate O₂ and the adsorption and activation of NH₃.

Key words: ammonia; silver; cerium; alumina oxide; supported catalyst; oxygen uptake; high resolution transmission electron microscopy; in situ diffuse reflectance infrared Fourier transform spectroscopy

The selective catalytic oxidation (SCO) of NH₃ to nitrogen (N₂) and water can reduce NH₃ emissions from chemi-

cal processes such as the selective catalytic reduction (SCR) of NO_x by NH₃ and from soda production [1-5]. In particu-

lar, the low temperature oxidation of NH_3 to N_2 has important environmental applications. Noble metals such as Pt and Ir are the most active but least selective [5–7]. Gang et al. [6,8] reported that an alumina-supported Ag (10 wt% Ag/ Al_2O_3) catalyst was extremely active for NH_3 oxidation at low temperatures, and was superior to the noble metals. Nonetheless, there is still a considerable need for better catalysts that are active at low temperatures. The addition of CeO_2 improves the NH_3 oxidation activities of Au-, Cu-, and Ag-based catalysts [2,3]. Lippits et al. [3] found that adding CeO_x to Ag-based catalyst lowered the temperature for the onset of oxidation from 300 to 200 °C. However, the role of CeO_2 in the Ag-based catalyst has not been studied in detail. Recently, we investigated the SCO of NH_3 over a 10 wt% Ag/ Al_2O_3 catalyst and discovered that the Ag valence state and particle size were significant for activity and N_2 selectivity at low temperatures [7]. To further improve the catalytic performance at low temperatures, we investigated the catalytic effects and the role of CeO_2 addition on Ag/ Al_2O_3 for the oxidation of NH_3 .

1 Experimental

1.1 Catalyst preparation and H_2 -pretreatment

The Ag-Ce/ Al_2O_3 catalysts used had different Ce loadings and were prepared by co-impregnating $\gamma\text{-Al}_2\text{O}_3$ powder (250 m^2/g) with appropriate amounts of AgNO_3 and $\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ in aqueous solution. After impregnation, excess water was removed in a rotary evaporator at 80 °C and the samples were dried overnight at 120 °C before calcination at 600 °C in air for 3 h. The mass ratio of Ag to $\gamma\text{-Al}_2\text{O}_3$ was maintained at 0.1 and the resulting Ag-Ce/ Al_2O_3 samples were designated as $\text{Ag}_{0.1}\text{Ce}_y/\text{Al}_2\text{O}_3$, where y was the Ce/ Al_2O_3 mass ratio. The catalysts were sieved to a particle size of 20–40 mesh and pretreated in a H_2/N_2 flow (20 vol% H_2 , 60 cm^3/min) at 400 °C for 2 h before testing.

1.2 Activity test

1.2.1 Steady state activity for NH_3 oxidation

The SCO activity was measured in a fixed-bed quartz reactor using 0.2 g catalyst. The reactant gas was obtained from blends of different gas flows at a combined flow rate of 200 cm^3/min ($W/F = 0.06$ ($\text{g}\cdot\text{s}/\text{cm}^3$)). A typical reactant gas composition was 0.05 vol% NH_3 and 10 vol% O_2 , with N_2 providing the balance. The individual NH_3 , O_2 , and N_2 flow rates were controlled by mass flow controllers. Inlet and outlet gas compositions were analyzed using an online NEXUS 670-FTIR spectrometer fitted with a 200 cm^3 gas

cell. N_2 balance was calculated using $M_{\text{NH}_3}(\text{inlet}) = M_{\text{NH}_3}(\text{outlet}) + 2M_{\text{N}_2\text{O}} + M_{\text{NO}_x} + 2M_{\text{N}_2}$. These operating conditions were used as the standard.

1.2.2 Evolution of NH_3 oxidation with time at various temperatures

A H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalyst was fed with the reactant mixture and kept at temperatures of 100 and 160 °C, respectively, to evaluate the activity of the catalyst under these different conditions. The evolution of NH_3 oxidation versus time was recorded at both 100 and 160 °C.

1.3 Characterization of catalyst

N_2 adsorption-desorption isotherms were obtained by the adsorption of N_2 at -196 °C using a Quantasorb-18 automatic instrument (Autosorb-1C, Quanta Chrome Instrument, USA). Specific areas were computed from these isotherms by the Brunauer-Emmett-Teller (BET) method. The pore size distribution was calculated using the Barrett-Joiner-Halenda (BJH) method. Before measurement, samples were degassed at 300 °C for 4 h.

Powder X-ray diffraction (XRD) scans of the catalysts were conducted in the 2θ range of 20° to 70° at a scan speed of 6°/min using a Rigaku D/max-RB X-ray diffractometer (Japan) with Cu K_α radiation, operating at 40 kV and 40 mA.

The surface structure and concentration of the active species on the catalysts were characterized by X-ray photoelectron spectroscopy (XPS). Spectra were recorded using a PHI Quantera spectrometer (ULVAC-PHI, Inc. USA) with Al K_α radiation ($h\nu = 1486.7$ eV). The binding energies were calibrated against the C 1s peak of C present as a contaminant on the catalyst (284.8 eV).

UV-Vis diffuse-reflectance spectra (UV-Vis DRS) were recorded under ambient conditions using a U-3010 (Hitachi, Japan) spectrometer with a standard diffuse reflectance unit. The scan range was 190–850 nm and the scan rate was 300 nm/min. The measured spectra were treated by Kubelka-Munk functions and deconvoluted into Gaussian peaks that were used for the quantitative assignment of different Ag and Ce species [9–18].

High-resolution transmission electron microscopy (HR-TEM) images were recorded on an H-800 (Hitachi, Japan) instrument. The accelerating voltage for the microscope was 200 kV, the point resolution was 0.204 nm, and 200–300 particles were counted to evaluate the particle size (diameter) distribution.

In situ diffuse reflectance infrared Fourier transform spectra (in situ DRIFTS) were recorded using a Nexus 670 (Thermo Nicolet) FT-IR spectrometer equipped with an in

situ diffuse reflection chamber and a high sensitivity mercury-cadmium-telluride (MCT) detector. A sample of ca. 30 mg was ground finely and placed into a ceramic crucible. A feed gas mixture, controlled by mass flow meters, was supplied at a flow rate of 100 cm³/min. The samples were first treated in a flow of high purity 10 vol% O₂/N₂ at 500 °C for 0.5 h and then cooled to room temperature, followed by H₂-pretreatment in a flow of H₂/N₂ (20 vol% H₂) at 400 °C for 1 h before being cooled to the desired temperature in a flow of high purity N₂. At each temperature, the background spectrum was recorded in flowing N₂, and it was subtracted from the sample spectrum obtained at the same temperature. All spectra were recorded at a resolution of 4 cm⁻¹ with 100 accumulated scans.

O₂ uptake was determined by O₂-pulse adsorption at various temperatures over H₂-pretreated Ag_{0.1}/Al₂O₃, Ce_{0.1}/Al₂O₃, and Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts using a Quantasorb-18 automatic instrument (Quanta Chrome Instrument Co, USA). Prior to the O₂-pulse adsorption, 300 mg sample was reduced in situ with a flow of 5 vol% H₂/Ar (40 cm³/min, 10 °C/min) at 400 °C for 2 h. Then He gas (40 cm³/min) was passed over the sample for 1.5 h. After cooling to the desired temperature in He, O₂ pulses (4.46 μmol) were injected into a He carrier flowing over the sample. The time intervals between the O₂ pulses were about 100 s. The O₂ signal was analyzed online with an Autosorb-1-C TCD controller.

2 Results and discussion

2.1 NH₃ oxidation over different Ag_{0.1}Ce_y/Al₂O₃ catalysts

After similar pretreatment, the catalysts (200 mg) were tested under standard conditions for their activities. The activities of the Ag_{0.1}Ce_y/Al₂O₃ catalysts with different Ce/Al₂O₃ mass ratios are illustrated in Fig. 1. The NH₃ conversion over Ce-promoted Ag/Al₂O₃ catalysts at low temperature was increased comparing with unpromoted Ag_{0.1}/Al₂O₃. However, although increasing the mass ratio to 0.1 enhanced NH₃ oxidation to the highest conversion, further increase of this ratio gave lower NH₃ conversion. This indicated that adding CeO₂ to Ag/Al₂O₃ improved the catalytic activity of Ag/Al₂O₃ at temperatures below 160 °C, and the best Ce/Al₂O₃ mass ratio was 0.1. The conversion of NH₃ using the Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst at 100 °C was 73%, which was significantly higher than the 30% obtained with unpromoted Ag_{0.1}/Al₂O₃ catalyst under standard conditions.

The effects of H₂-pretreatment and the effects of CeO₂ on NH₃ oxidation at low temperatures over the Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst were also investigated (results not shown here) by comparing the activities of H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃,

Fig. 1. Catalytic performance of the H₂-pretreated Ag_{0.1}Ce_y/Al₂O₃ catalysts with different Ce/Al₂O₃ mass ratios for NH₃ oxidation at different temperatures. Reaction conditions: NH₃ 0.05 vol%, O₂ 10 vol%, N₂ as balance, flow rate 200 cm³/min, catalyst 0.2 g (W/F = 0.06 (g·s)/cm³).

Ce_{0.1}/Al₂O₃, and fresh Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts. Both the fresh Ag_{0.1}Ce_{0.1}/Al₂O₃ and H₂-pretreated Ce_{0.1}/Al₂O₃ catalysts showed little or no activity below 160 °C, while high NH₃ conversion occurred with the H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst at temperatures below 160 °C. Clearly, H₂-pretreatment enhanced significantly the low temperature activity of Ag_{0.1}Ce_{0.1}/Al₂O₃, although Ce_{0.1}/Al₂O₃ was inactive at low temperatures (≤160 °C). The stability of H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ for NH₃ oxidation was evaluated at 100 and 160 °C. The results are shown in Fig. 2. NH₃ conversion at 100 °C decreased gradually over 48 h from 73% to 37%, while the 100% NH₃ conversion at 160 °C continued for more than 96 h.

Fig. 2. Stability test of the H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst at various temperatures. Reaction conditions: NH₃ 0.05 vol%, O₂ 10 vol%, N₂ as balance, flow rate 200 cm³/min, catalyst 0.2 g (W/F = 0.06 (g·s)/cm³).

The performance of Ag_{0.1}Ce_{0.1}/Al₂O₃ was also compared with the reported results from Ag/Al₂O₃ and other noble metal catalysts [7]. The performance of Ag_{0.1}Ce_{0.1}/Al₂O₃

was superior to that of the Ag/Al₂O₃ and other noble catalysts at low temperatures and its N₂ selectivity (about 50% at temperatures below 160 °C) was similar to that of Ag/Al₂O₃. N₂O was the main by-product over Ag_{0.1}Ce_{0.1}/Al₂O₃ at low temperatures. With further improvement, this catalyst would be promising as a suitable catalyst at low temperatures (≤ 160 °C).

2.2 Characterization results

2.2.1 N₂ physisorption

The effects of CeO₂ addition on the textural characteristics of the co-impregnated Ag/Al₂O₃ samples were assessed by measuring N₂ adsorption-desorption isotherms. The results are shown in Table 1. The BET surface area, pore size, and pore volume of the Ce-promoted Ag/Al₂O₃ catalysts decreased with increasing Ce/Al₂O₃ ratio. At lower Ce loadings, the decrease in pore size can be attributed to the blockage by Ce species formed from excess Ce. At higher Ce loadings, this could be due to the smaller pores of CeO₂ deposited on the Al₂O₃ surface. The results showed that the activities of the Ag_{0.1}Ce_{*y*}/Al₂O₃ catalysts at low temperatures (Fig. 1) were not related to their BET surface areas.

Table 1 BET surface area and pore size of Ag_{0.1}Ce_{*y*}/Al₂O₃ catalysts with different Ce/Al₂O₃ mass ratios

Sample	Surface area (m ² /g)	Pore volume (cm ³ /g)	Average pore diameter (nm)
Al ₂ O ₃	250	0.81	13.0
Ag _{0.1} Ce ₀ /Al ₂ O ₃	249	0.80	12.9
Ag _{0.1} Ce _{0.05} /Al ₂ O ₃	205	0.65	12.7
Ag _{0.1} Ce _{0.1} /Al ₂ O ₃	206	0.63	12.2
Ag _{0.1} Ce _{0.15} /Al ₂ O ₃	197	0.53	10.8
Ag _{0.1} Ce _{0.2} /Al ₂ O ₃	173	0.52	12.0
Ag _{0.1} Ce _{0.3} /Al ₂ O ₃	168	0.42	10.1

2.2.2 XRD

The XRD patterns of the Ag_{0.1}Ce_{*y*}/Al₂O₃ catalysts are shown in Fig. 3. In the unpromoted Ag/Al₂O₃, γ -Al₂O₃ was the only phase. With the Ce-promoted samples, diffraction lines from CeO₂ were present in addition to those of γ -Al₂O₃. The intensities of the CeO₂ lines became stronger and sharper with increasing Ce loading, demonstrating that the size of the CeO₂ particles on the γ -Al₂O₃ matrix increased with increasing Ce loading leading to a decrease in CeO₂ dispersion. This coincided with the decrease in BET surface area (Table 1). As shown in Fig. 1, the activity of the Ag_{0.1}Ce_{*y*}/Al₂O₃ catalyst at low temperatures first increased with increasing Ce loading ($y \leq 0.1$), then decreased at higher loadings. This implied that a suitable Ce loading (y

Fig. 3. XRD patterns of the fresh Ag_{0.1}Ce_{*y*}/Al₂O₃ catalysts with different Ce/Al₂O₃ mass ratios.

≤ 0.1) gave the best dispersion of CeO₂ in Ag_{0.1}Ce_{*y*}/Al₂O₃, which gave the highest NH₃ conversion at low temperatures. Conversely, the reduced dispersion of CeO₂ at higher Ce loadings ($y > 0.1$) was one cause for the decrease in NH₃ oxidation activity over the Ag_{0.1}Ce_{*y*}/Al₂O₃ catalysts at temperatures below 160 °C.

2.2.3 XPS

XPS was used to determine the element compositions and their chemical valences on the surfaces of fresh, H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts and the samples after the stability test. The results for Ag are not shown here, but previous data [4] indicated that the binding energies of the 3*d* electrons in Ag⁰, Ag⁺, or Ag²⁺ were similar. Therefore, it was difficult to get the oxidation state of the Ag species from the XPS results. Instead, these were obtained from UV-Vis DRS results.

The experimental and fitted Ce 3*d* spectra of the catalysts are shown in Fig. 4. The broad line for the Ce 3*d* core level indicated that both Ce³⁺ and Ce⁴⁺ existed. The curves were fitted with eight peaks, which corresponded to the four pairs of spin-orbit doublets [19–21]. The letters V and U refer to the Ce 3*d*_{5/2} and Ce 3*d*_{3/2} spin-orbit components, respectively. The relative percentage of the two Ce species was obtained from the area ratio of the Ce⁴⁺ 3*d*_{5/2} (V, V', V'') relative to Ce³⁺ 3*d*_{5/2} (V').

Table 2 shows the results of the XPS quantitative analysis based on the atomic ratios obtained. The chemical valence of Ce on the surface of fresh Ag_{0.1}Ce_{0.1}/Al₂O₃ was mainly Ce⁴⁺ with a small Ce³⁺ component. The surface ratio of Ce⁴⁺/Ce³⁺ on fresh Ag_{0.1}Ce_{0.1}/Al₂O₃ decreased with H₂-pretreatment, with some surface Ce⁴⁺ reduced to Ce³⁺. The surface ratio of Ce⁴⁺/Ce³⁺ increased during the stability test at 100 °C for 48 h (4.6), which indicated that some Ce³⁺

Fig. 4. Experimental and fitted Ce 3d XPS profiles for Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts: (a) H₂-pretreated; (b) Kept at 100 °C for 48 h; (c) Kept at 160 °C for 96 h; (d) Fresh catalyst.

was gradually oxidized at 100 °C over 48 h. In addition, the surface ratio of Ce⁴⁺/Ce³⁺ increased further after testing at 160 °C for 96 h (5.2), which demonstrated that more Ce³⁺ was oxidized at the higher temperature with the longer period of time. Taking into account this and the activity test results shown in Fig. 2, it can be seen that while NH₃ conversion at 100 °C decreased gradually together with the partial oxidation of Ce³⁺ in which Ce⁴⁺/Ce³⁺ was increased to 4.6, the conversion did not decrease at the higher temperature of 160 °C despite more partial oxidation of Ce³⁺ in which Ce⁴⁺/Ce³⁺ was increased to 5.2.

Table 2 XPS data (Ce⁴⁺/Ce³⁺) from the Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts in Fig. 4

Ag _{0.1} Ce _{0.1} /Al ₂ O ₃ catalyst	Ce ⁴⁺ /Ce ³⁺
H ₂ -pretreated	4.4
Retained at 100 °C for 48 h	4.6
Retained at 160 °C for 96 h	5.2
Fresh	6.3

2.2.4 UV-Vis DRS

The results of the UV-Vis DRS confirmed the details of the state of the supported Ag and Ce species. Fig. 5 shows the UV-Vis DRS of the fresh, H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst and two samples after stability test as described above. The UV-Vis DRS analysis demonstrated the existence of different states of the Ag and Ce species, which can be seen after subtraction of the Al₂O₃ spectrum. Fresh Ag_{0.1}Ce_{0.1}/Al₂O₃ showed broad absorption bands at 206, 220, 260, and 305 nm, while the other three samples had an additional broad band at 450 nm (Fig. 5(a)). The bands at 206, 450, and 260 nm can be attributed to highly dispersed Ag⁺ ions, metallic silver (Ag⁰) particles

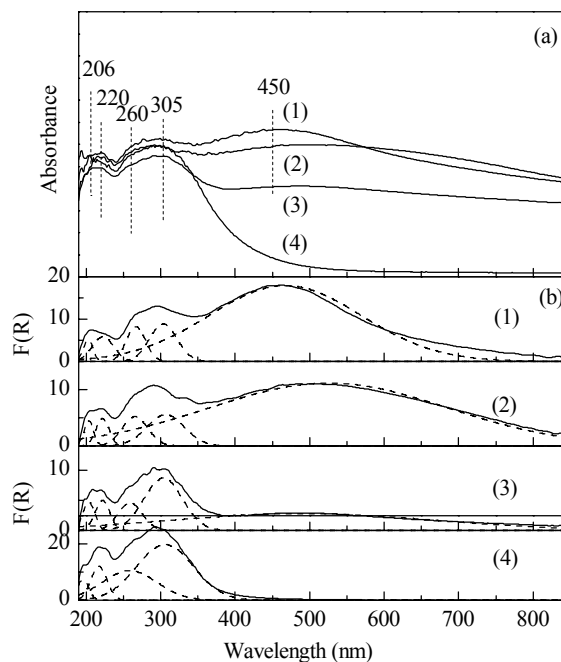

Fig. 5. Diffuse reflectance UV-Vis spectra (a) and deconvoluted subbands (b) of the Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts. (1) H₂-pretreated; (2) Retained at 100 °C for 48 h; (3) Retained at 160 °C for 96 h; (4) Fresh catalyst.

[9–15], and Ce³⁺ [17,18], respectively. The bands at 220 and 305 nm can be attributed to Ce⁴⁺ [16–18].

In Fig. 5(b), the measured spectra of the Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts have been treated by Kubelka-Munk functions and deconvoluted into Gaussian peaks assigned to different Ag and Ce species [9–18]. Deconvolution was performed based on the above assignments. The relative intensities of these peaks are listed in Table 3, along with the quantification results for the different Ag and Ce species: *I*₁ for Ag⁺ (band at λ < 238 nm), *I*₂ for Ag⁰ (λ > 350 nm), *I*₃ for Ce³⁺ (250 nm < λ < 300 nm), and *I*₄ for Ce⁴⁺ (210 nm < λ < 250 nm and 260 nm < λ < 350 nm). Although the peaks can be used to give a semi-quantitative description of the distribution of the different species, the quantification results shown in Table 3 provides a better comparison of the relative amounts of the various Ag and Ce species on the catalysts.

Table 3 Percentage of integrated area of the peaks derived from deconvolution of the UV-Vis DRS in Fig. 5

Ag _{0.1} Ce _{0.1} /Al ₂ O ₃ catalyst	<i>I</i> ₁ ^a /%	<i>I</i> ₂ ^b /%	<i>I</i> ₃ ^c /%	<i>I</i> ₄ ^d /%
Fresh	100	0	12.5	87.5
H ₂ -pretreated	1.8	98.2	27.6	72.4
Retained at 100 °C for 48 h	2.0	98.0	23.3	77.7
Retained at 160 °C for 96 h	7.3	92.7	21.5	78.5

^aFor Ag⁺ (band at λ < 238 nm).

^bFor Ag⁰ (band at λ > 350 nm).

^cFor Ce³⁺ (band at 250 nm < λ < 300 nm).

^dFor Ce⁴⁺ (band at 210 < λ < 250 nm and 260 < λ < 350 nm).

The UV-Vis DRS results (Fig. 5) also confirmed that Ce^{3+} and Ce^{4+} coexisted on the alumina support. Furthermore, the relative amount of Ce^{4+} decreased following H_2 -pretreatment but increased slightly following the stability test for 48 h at 100 °C and then increased more significantly after the stability test for 96 h at 160 °C. This was in agreement with the XPS results (Table 2). It can be concluded that some Ce^{3+} on the surface of the H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalyst was oxidized to Ce^{4+} at both 100 and 160 °C during the stability test, but the relative amounts of Ce^{4+} were lower than that in the fresh catalyst.

In fresh $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$, Ag^+ was the major Ag species present. On the H_2 -pretreated catalyst, Ag^0 was the main Ag species present (Table 3), showing that most Ag_2O on the support was reduced to Ag^0 by the H_2 -pretreatment. Taken together with the activity test results shown in Fig. 1, this showed that high NH_3 conversion was obtained over the H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalyst in the temperature range of 100–160 °C with the presence of Ag^0 , while almost no NH_3 conversion was observed over the H_2 -pretreated $\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ or fresh $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ due to the absence of Ag^0 . That is, the presence of Ag^0 explains the enhanced low temperature activity of the H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalyst. It can therefore be concluded that Ag^0 is the main active species on this catalyst that is responsible for NH_3 oxidation at temperatures below 160 °C. However, a comparison with the H_2 -pretreated $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$ catalyst showed the H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalyst has a much higher NH_3 conversion in the presence of Ce. This showed that Ce has an important role in NH_3 oxidation at low temperature. This will be discussed in detail in the following section.

It was also found that Ag^0 was slightly oxidized after the stability test for more than 48 h at 100 °C while some Ce^{3+} on the surface of the catalyst was oxidized to Ce^{4+} under the same conditions. During this time, NH_3 conversion decreased gradually (Fig. 2). Consequently, Ce^{3+} oxidation can partly explain the decrease in catalytic activity at 100 °C with H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$.

It is worth noting that both Ag^0 and Ce^{3+} were partly oxidized during the stability test at 160 °C for 96 h (Fig. 5), but that 100% NH_3 conversion was maintained throughout (Fig. 2).

2.2.5 HR-TEM

The HR-TEM images shown in Fig. 6 for the H_2 -pretreated $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$ and $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalysts show the surface distribution of Ag particles. Statistical calculations of Ag particle size measured from these images provided the mean particle size (d) and degree of Ag dispersion (Table 4). The particles were assumed to be spherical.

Fig. 6. HR-TEM images of the H_2 -pretreated $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$ (a) and $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ (b) catalysts.

Table 4 Ag dispersion (D), mean particle size (d), and turnover frequency (TOF) of H_2 -pretreated $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$ and $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalysts at 100 °C

Catalyst	d^a/nm	$D^b/\%$	TOF ^c ($10^{-3}/\text{s}$)
$\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$	4.6	29.0	0.36
$\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$	5.2	25.5	1.61

Reaction conditions: catalyst 0.2 g, NH_3 0.05 vol%, O_2 10 vol%, total flow rates 200 cm^3/min , temperature 100 °C.

^aDetermined by HR-TEM.

^bSpherical Ag crystallites are assumed, and the relationship between crystallite diameter size (d) and dispersion D is $d = 1.34/D$ [22].

^cCalculated as moles of NH_3 converted per mole of Ag on the whole catalyst per second.

The relationship between the crystallite diameter (d) and Ag dispersion (D) was $d = 1.34/D$ [22]. H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ had a Ag mean particle size of 5.2 nm, which is similar to that of $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$ (4.6 nm). This is consistent with the previous results based on O_2 chemisorption [7]. The Ag dispersion had to be determined by HR-TEM based on a H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ catalyst because reduced CeO_x chemisorbs O_2 .

It was found that Ag^0 was the main active species involved in NH_3 oxidation in H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ at temperatures below 160 °C, which was in agreement with previous results on H_2 -pretreated $\text{Ag}/\text{Al}_2\text{O}_3$ [7]. The HR-TEM images from the present study showed that H_2 -pretreated $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ and $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$ both had similar Ag dispersions. The turnover frequency (TOF) for NH_3 at 100 °C (Table 4), however, showed that $\text{Ag}_{0.1}\text{Ce}_{0.1}/\text{Al}_2\text{O}_3$ had a better activity than $\text{Ag}_{0.1}/\text{Al}_2\text{O}_3$.

These results indicated that Ag dispersion is not the primary contribution to the difference in activity observed between these two samples at low temperature. Indeed, the enhanced activity at low temperatures may be primarily linked to the role of the Ce species.

2.3 In situ DRIFTS study of NH₃ adsorption

In order to investigate the role of Ce and Ag for the adsorption of NH₃ on the catalysts, in situ DRIFTS spectra for the H₂-pretreated Ce_{0.1}/Al₂O₃ and Ag_{0.1}Ce_{0.1}/Al₂O₃ catalysts exposed to NH₃ are shown in Fig. 7. In Fig. 7(a), the bands at 1695, 1481, and 1392 cm⁻¹ are from the deformation modes of NH₄⁺ formed by the interaction of NH₃ with Brønsted acid sites on γ-Al₂O₃ [2,23–27]. The bands at 1608 and 1240 cm⁻¹ can be attributed to the asymmetric and symmetric deformation modes, respectively, of NH₃ molecules coordinated on Lewis acid sites of the γ-Al₂O₃ [23–27]. The band at 1456 cm⁻¹ can be attributed to imide (–NH) deformation modes [2,28,29]. The two shoulders at 1580 and 1376 cm⁻¹ can be assigned to amide (–NH₂) scissoring and (–NH₂) wagging, respectively [2,28,29]. The bands in the N–H stretching region also occur at 3401, 3356, 3270, and 3149 cm⁻¹ [28,29].

The band intensities from NH₃ coordinated on Brønsted (1695, 1481, and 1392 cm⁻¹) and Lewis acid sites (1608 and 1240 cm⁻¹) decreased gradually with increasing temperature. Those related to –NH₂ and –NH (1580, 1456, and 1376 cm⁻¹) appeared at room temperature together with those of NH₃, but disappeared at higher temperatures (Fig. 7(a)). These results showed that NH₃ adsorbed on H₂-pretreated

Ce_{0.1}/Al₂O₃ was adsorbed dissociatively to form –NH₂ and –NH intermediates and followed reactions (1) and (2) with the abstraction of hydrogen. Furthermore, these –NH₂ and –NH are stable on H₂-pretreated Ce_{0.1}/Al₂O₃ and do not disappear until a temperature of 400 °C.

In the case of the H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst, similar bands occurred at 1695, 1608, 1481, 1456, 1392, 1365, and 1240 cm⁻¹ following NH₃ adsorption (Fig. 7(b)). The bands of NH₃ adsorbed on the Brønsted and Lewis acid sites of Ag_{0.1}Ce_{0.1}/Al₂O₃ disappeared at 160 °C. While the intensity of these bands decreased with increasing temperature, the bands corresponding to –NH₂ (1365 cm⁻¹) and –NH (1456 cm⁻¹) increased and then disappeared at temperatures below 160 °C, indicating that NH₃ adsorbed on H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ was activated to form –NH₂ and –NH intermediates first and then desorbed from the surface of the catalyst. Comparing with the in situ DRIFTS results in Fig. 7(a), it is seen that the adsorbed NH₃ on both H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ and Ce_{0.1}/Al₂O₃ can be activated to form –NH₂ and –NH intermediates, but the –NH₂ and –NH formed can be activated and desorbed from the surface of H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ much faster in the presence of Ag⁰. In addition, according to our previous in situ DRIFTS results of NH₃ adsorption on H₂-pretreated Ag_{0.1}/Al₂O₃ [30], bands corresponding to –NH₂ and –NH did not appear at room temperature, which is different from that with H₂-pretreated Ce_{0.1}/Al₂O₃. Hence, we conclude that CeO₂ addition promoted the dissociative adsorption of NH₃ to form –NH₂ and –NH intermediates.

Fig.7. In situ DRIFTS spectra of the adsorbed species arising from contact of NH₃ (0.05 vol%) with the H₂-pretreated Ce_{0.1}/Al₂O₃ (a) and Ag_{0.1}Ce_{0.1}/Al₂O₃ (b) at room temperature and successive purging with N₂ at various temperatures.

Fig. 8. O_2 uptakes on the H_2 -pretreated $Ag_{0.1}/Al_2O_3$, $Ce_{0.1}/Al_2O_3$, and $Ag_{0.1}Ce_{0.1}/Al_2O_3$ catalysts at $100\text{ }^\circ\text{C}$.

2.4 O_2 -pulse adsorption

The O_2 uptakes of the catalysts were determined by measuring O_2 -pulse adsorption at $100\text{ }^\circ\text{C}$. As shown in Fig. 8, O_2 was chemisorbed on the three catalysts. As expected, the amount of O_2 uptake on $Ag_{0.1}Ce_{0.1}/Al_2O_3$ ($69.71\text{ }\mu\text{mol/g}$) was much higher than that on either $Ag_{0.1}/Al_2O_3$ ($45.73\text{ }\mu\text{mol/g}$) or $Ce_{0.1}/Al_2O_3$ ($36.47\text{ }\mu\text{mol/g}$).

Gang et al. [6,8] reported on adsorbed atomic oxygen (O) on reduced Ag catalysts, and considered the dissociation of O_2 to be the rate controlling step in NH_3 oxidation [8]. Leferts et al. [31] also detected O on a H_2 -pretreated Ag surface. From the present O_2 -pulse adsorption results, it is likely that some molecular O_2 was chemisorbed dissociatively on the surface of H_2 -pretreated $Ag_{0.1}/Al_2O_3$ as O species.

Li et al. [32] reported that molecular O_2 was adsorbed on the surface of partially reduced cerium oxide to form a superoxide species (O_2^-), which can be further chemisorbed dissociatively to O on the surface of H_2 -reduced cerium oxide. In the present study, some surface Ce^{4+} of the H_2 -pretreated $Ag_{0.1}Ce_{0.1}/Al_2O_3$ was reduced to Ce^{3+} by H_2 reduction (Tables 2 and 3). This can lead to the formation of surface oxygen nests together with bulk oxygen vacancies, to result in the dissociative adsorption of O_2 on reduced cerium oxide. Taken together with the O_2 pulse-adsorption results (Fig. 8), it can be concluded that some molecular O_2 is chemisorbed dissociatively to form O on the surface of H_2 -pretreated $Ce_{0.1}/Al_2O_3$, which would explain the enhanced O_2 uptake on the H_2 -pretreated $Ag_{0.1}Ce_{0.1}/Al_2O_3$

catalyst.

From these results, it can be concluded that adding CeO_2 enhanced the O_2 uptake of Ag/Al_2O_3 by promoting the catalytic ability of Ag/Al_2O_3 for dissociative or non-dissociative adsorption of O_2 at low temperatures ($100\text{ }^\circ\text{C}$). The NH_3 oxidation activity of Ag/Al_2O_3 at low temperatures is determined by its catalytic ability for both dissociative and non-dissociative adsorption of O_2 [6]. Chemisorbed O enhanced NH_3 oxidation below $140\text{ }^\circ\text{C}$ on Ag/Al_2O_3 , while gas phase molecular O_2 mainly interacted with adsorbed NH_3 at temperatures above $140\text{ }^\circ\text{C}$ [30]. From Fig. 1 it can be seen that higher NH_3 conversion occurred on H_2 -pretreated $Ag_{0.1}Ce_{0.1}/Al_2O_3$, with a higher O_2 uptake at $100\text{ }^\circ\text{C}$. This confirmed that O_2 uptake was the main factor causing the enhanced low temperature activity of the catalyst, since the addition of CeO_2 improved the activation of O_2 to form O at $100\text{ }^\circ\text{C}$. In addition, our previously reported results [30] showed that O favors the activation of adsorbed NH_3 to form $-NH$ and $-HNO$ intermediates (reactions (3)–(5)), which are the key intermediates for NH_3 oxidation (route (6) and (7)) at low temperatures ($< 140\text{ }^\circ\text{C}$).

Hence, we conclude that adding CeO_2 to Ag/Al_2O_3 improved the catalyst's ability in the adsorption and activation of O_2 to form O. Then the O species activated adsorbed NH_3 to form $-NH$ and $-HNO$ intermediates. Our in situ DRIFTS results also proved that adding CeO_2 favored the dissociative adsorption of NH_3 to form $-NH_2$ and $-NH$ (reactions (1) and (2)), giving the reason for the enhanced activity of the H_2 -pretreated $Ag_{0.1}Ce_{0.1}/Al_2O_3$ at temperatures below $160\text{ }^\circ\text{C}$.

The $100\text{ }^\circ\text{C}/48\text{ h}$ stability test results (Fig. 2) showed that the high degree of NH_3 conversion decreased gradually with the oxidation of some Ce^{3+} (Tables 2 and 3), although Ag^0 showed little oxidation under these conditions. This presumably reflected a decrease in the ability of the catalyst to participate in the dissociative adsorption of O_2 as a result of the oxidation of Ce^{3+} , thus contributing to a decrease in NH_3 oxidation activity at $100\text{ }^\circ\text{C}$.

The $160\text{ }^\circ\text{C}/96\text{ h}$ stability test results, however, showed that 100% NH_3 conversion was maintained throughout (Fig. 2), although both Ag^0 and Ce^{3+} were partly oxidized during the test (Fig. 5). Gas phase molecular O_2 mainly interacted with adsorbed NH_3 at temperatures above $140\text{ }^\circ\text{C}$ on Ag/Al_2O_3 [30]. Hence, it can be inferred that at the higher temperature of $160\text{ }^\circ\text{C}$, adsorbed NH_3 mainly interacted with O_2 on $Ag_{0.1}Ce_{0.1}/Al_2O_3$ and any partial oxidation of Ce^{3+} did not affect the activity under these conditions. Furthermore,

Ag⁺ is the active species on Ag/Al₂O₃ at temperatures above 140 °C [7], and thus Ag⁺ on Ag_{0.1}Ce_{0.1}/Al₂O₃ is likely also the active species involved in NH₃ oxidation at 160 °C. Hence, high NH₃ conversion will persist in spite of the oxidation of some Ag⁰ species.

3 Conclusions

The addition of an appropriate amount of CeO₂ to Ag/Al₂O₃ improved the catalytic oxidation of NH₃ at temperatures below 160 °C. Ag⁰ is the main active species on a H₂-pretreated Ag_{0.1}Ce_{0.1}/Al₂O₃ catalyst. It is responsible for the adsorption and activation of NH₃ and O₂ simultaneously at temperatures below 160 °C. The addition of CeO₂ enhanced the catalyst's ability to adsorb and activate O₂ to O, the O to further activate adsorbed NH₃, and also the dissociative adsorption of NH₃. This was the main reason for the enhancement of NH₃ oxidation at low temperatures (≤ 160 °C) over Ag_{0.1}Ce_{0.1}/Al₂O₃.
